

Rapidly Aging Populations: Russia/Eastern Europe

Natalia S. Gavrilova and Leonid A. Gavrilov

Regional dimensions and trends in population aging: Russia/Eastern Europe

Population aging is a global phenomenon and countries of Eastern European also experience rapid increase in the proportion of older people. The proportion of elderly people in the Eastern Europe is currently lower than in the European region as a whole. However this population aging is expected to continue over the next few decades, eventually leading to the convergence in the proportion of older people in the countries of Eastern and Western Europe.

Aging of population is often measured through an increase in the percentage of elderly people of retirement ages. A society is considered to be relatively old when the fraction of the population aged 65+ years exceeds 8-10% (Kinsella and Velkoff 2001). According to this definition, the populations of the Eastern Europe and Russia are becoming very old, because the percentage of elderly people reached the levels of 14.2% and 13.8% correspondingly in 2005, and it is expected to increase further. The choice of the boundary for old age (65 years and over) is rather arbitrary therefore many demographers who study Eastern European countries also use 60 years cut-off (retirement age for many countries of the Eastern Europe). In this case a population is considered to be old, when the proportion aged 60+ years exceeds 10-12% (Kinsella and Velkoff 2001). Table 1 presents data on the proportion of population age sixty and over for selected countries. Note that populations of Bulgaria, Hungary and Ukraine were older than the population of the European region in 2005. In addition to these three

countries, Czech Republic, Romania and Belarus have older populations than the Eastern European region.

TABLE 1 ABOUT HERE

Proportion of very old population (80+) in all Eastern European countries is still lower than in European region (Table1), which may be explained by rather high mortality of the oldest age groups in these countries compared to Western Europe.

Figure 1 shows the trends in the proportion of people aged 60 years and over for the Eastern Europe and Russia compared to the European region. Note that the fastest growth in the proportion of elderly in Russia and the Eastern Europe occurred in the 1990s and now both of them experience a slow decline in the proportion of people aged 60 years and over.

FIGURE 1 ABOUT HERE

A useful indicator of age structure and population aging is the aging index (sometimes referred to as the elder-child ratio), defined as the number of people aged 65 and over per 100 youths under age 15 (see Table 2). In 1975 all countries of the Eastern Europe had more youth than elderly (aging index below 100). Now all of them except Moldova have more elderly than youth. By 2030 all countries of Eastern Europe have a projected aging index of at least 100, and Bulgaria and Czech Republic are in excess of

200 (Kinsella and Velkoff 2001). The aging index also is useful in examining within-country differences in the level of population aging (Kinsella and Velkoff 2001).

TABLE 2 ABOUT HERE

The second class of indicators for population aging is the group of statistical measures of location (median, mean and modal ages of population). The median age is used particularly often as an indicator of the general age of people in some areas. Median age of population is the age at which exactly half the population is older and another half is younger. The 2005 median age in Europe was 39 years (Table 2), indicating that the number of people under age 39 equals the number, who have already celebrated their 39th birthday. It is the simplest and most widely used indicator of the age of any population. Table 2 shows that population of the Eastern Europe has lower median age (37.5) than population of the European region. At the same time, population of Bulgaria has higher median age than population of Europe and Ukraine and Czech Republic have the same median age as Europe (Table 2). This indicator is also useful to monitor changes in population aging over time. Table 2 shows the increase in median age of Eastern European countries from 1975 to 2005. Note that the Eastern Europe aged slower in the 1990s than the European region as a whole. However Bulgaria, Belarus and Slovakia demonstrated particularly high pace of population aging.

Figure 2 shows time trends in median ages of populations of the European region, Eastern Europe and Russia. In contrast to the proportion of elderly (Figure 1) this demographic indicator does not show any recent decrease in population aging of both

Eastern Europe and Russia. It demonstrates that the fastest population aging in the Eastern Europe and Russia happened in the 1950s and the 1960s.

FIGURE 2 ABOUT HERE

The main problem in describing population aging is that any its single indicator may be misleading, because the age distribution of population is often very irregular, reflecting the scars of the past events (wars, economic crises etc.), and it cannot be described just by one number without significant loss of information. Therefore, perhaps the most adequate approach to study population aging is to explore the age distribution through a set of percentiles, or graphically by analyzing the population pyramids. The latter approach is particularly useful for countries of the Former Soviet Union (Russia, Ukraine, Belarus, Moldova), which experienced low fertility during the World War II with a subsequent increase in births during the postwar period. These population waves affected proportions of later generations in these countries when WWII and postwar generations reached reproductive ages.

Demographic determinants of population aging in the Eastern Europe

Decline in fertility. Demographic studies demonstrated that the declining fertility (birth) rates have the greatest role in causing population aging (Gavrilov and Heuveline 2003; Kinsella and Velkoff 2001). Particularly rapid population aging, which is expected to occur in the Eastern Europe and Russia after 2010 will mainly be due to fewer children

born after the peak of the high postwar fertility. Population aging happens because the declining fertility (birth) rates make recent cohorts smaller than the preceding ones, thus tilting the age distribution towards older ages. Future changes in the rate of population aging will be conditioned by different sizes of birth cohorts entering and leaving reproductive ages.

Acceleration of population aging in Russia and Eastern Europe in the 1990s was also caused by low fertility during the period of economic transition in these countries. The period after 1989 witnessed a profound transformation in childbearing patterns in the countries of the Eastern Europe, including a rapid decline in fertility rates, the postponement of childbearing, and an upsurge in the proportion of extramarital births (Sobotka 2003). Currently all countries of Eastern Europe demonstrate fertility below the European level (Table 3).

TABLE 3 ABOUT HERE

Researchers believe that the intensive decline of the total fertility rates seems to indicate a uniform reaction of former Communist societies to the ongoing social and economic changes during the early 1990s and note increasing diversity in current fertility patterns across the region (Sobotka 2003). It is believed that the more rapid postponement of parenthood was related to the success of the transition period bringing more opportunities and choices for young people and shifting the institutional structure of many Eastern European societies considerably closer to the structure of western European countries (Sobotka 2003). On the other hand, in many FSU countries like

Ukraine, fertility declined to very low levels without a transition to a later pattern of childbearing, which is explained by persistence of traditional norms for childbearing and the roles of men and women in this country (Perelli-Harris 2005).

Increasing longevity. The effects of increasing human life span on population aging are more complex. The increase in life expectancy has two components, acting on population aging in the opposite directions. The first component is the mortality decline among infants, children and relatively young persons, having age below the population mean. This component of mortality decline is acting against population aging, because its effects (saving young lives) are similar to effects of increased fertility (Preston, Heuveline and Guillot 2001). Thus, the increase in life expectancy in Russia Eastern European countries during the postwar period led to partial alleviation of population aging, because mortality decline in such countries was concentrated in the younger age groups. The second component of the increase in life expectancy is related to a new trend of mortality decline, which had emerged after the 1950s in the developed countries -- an accelerating decrease in mortality rates among the oldest-old (85+ years), and the oldest-old women in particular (Gavrilov and Gavrilova 1991; Kannisto et al. 1994). This second component of mortality decline, which is concentrated in older age groups, is becoming an important determinant of population aging (women in particular) in industrialized countries. However this component did not play a significant role in the aging of Russian and Eastern European populations so far. All these countries did not demonstrate a significant increase in life expectancy during the last decades and some of these countries (Russia, Belarus, Ukraine) demonstrated even a decrease in life

expectancy compared to 1990. All countries of the Eastern Europe and the Former Soviet Union with exception of Czech Republic and Slovakia have life expectancy below the European level (Table 3). There is also diversity in mortality trends and patterns across these countries. After a period of stagnating or even improving mortality in the 1980s, many countries of Eastern Europe experienced mortality crisis in the early 1990s after the fall of Communism (Nolte, McKee and Gilmore 2005). In the Eastern European countries the increase of mortality did not last long and was replaced by mortality decline and growth in life expectancy. Now many countries of the Eastern Europe demonstrate rapid decline in mortality at older ages (Mesle and Vallin 2006), so one may expect an increasing role of mortality decline as a contributing factor of population aging in these countries. Countries of the Former Soviet Union (Russia, Moldova, Ukraine and Belarus) demonstrated another patterns of mortality during the 1990s. Mortality fluctuations in these countries (with exception of Belarus) followed in great extent the mortality pattern observed in Russia (Andreev 1999; Andreev 2001) reflecting economic crises in this country (Gavrilova et al. 2000). Now life expectancy in FSU countries shows either decrease or stagnation at very low level (Nolte et al. 2005). In the beginning of the 1990s, Belarus had the highest life expectancy among the FSU countries mentioned above (Andreev 2001). However this advantage was lost due to gradual decline in life expectancy during the late 1990s and early 2000s (Andreev 2001). The uncertainty in the future of mortality changes in FSU countries affects the quality of demographic forecasts of population aging in the countries of the Former Soviet Union.

It is useful to consider population aging in a broader context of demographic transition when society moves from a situation of high rates of fertility and mortality to

one of low rates. This transition is characterized first by declines in infant and childhood mortality as infectious and parasitic diseases are reduced. Other things being equal, this initial decline in mortality generates a younger population age structure. Then, when fertility starts to decline, populations begin to age. At the next step population aging is accelerated further, when the late-life mortality rates also start to decline. This combined synergistic effect of fertility decline and old-age mortality decline is known as double aging process (Gavrilov and Heuveline 2003; Kinsella and Velkoff 2001). Demographic transition in Russia and countries of the Eastern Europe started later than in the Western Europe. As a result, Russian and Eastern European populations are younger than populations of the rest of the Europe. Most countries of the Eastern Europe lag behind the Western Europe in their improvement of mortality at older ages. In some countries (Russia, Belarus, Ukraine) the process of rapid mortality decline at older ages is yet to be observed, so that the double aging process in these countries is a possibility of a remote future.

Migration. The rate of population aging may also be modulated by migration.

Immigration usually slows down population aging, because immigrants tend to be younger. On the other hand, emigration of working-age adults accelerates population aging, as it is observed now in many Eastern European nations. The Eastern European countries are not uniform in the direction and size of migrant flows (see Table 3). For example Czech Republic and Hungary have positive net migration (Kaczmarczyk and Okolski 2005). On the other hand, Moldova, Romania, Poland and Ukraine lose their population due to migration (Kaczmarczyk and Okolski 2005). Emigration of young

people may significantly accelerate population aging as it happened in Bulgaria (Hristov 2004). Russia is the largest country in the region accepting immigrants (Kaczmarczyk and Okolski 2005) and has the second largest flow of immigrants after the United States (Mansoor and Quillin 2007). Immigration to Russia from other countries (mainly from the countries of the Former Soviet Union) helps to alleviate the effects of population aging. Within Russia the migration processes accelerate population aging in rural regions of European North and Center (due to out-migration of youth) and slow down it in big cities like Moscow. Some demographers expect that migration will have a more prominent role in population aging in the future, particularly in low-fertility countries with stable or declining population size. For example, demographers at the Center of Demography and Human Ecology in Russia believe that immigration may help to slow down both population aging and depopulation in Russia (Vishnevskiy 2006).

Table 3 shows effects of fertility and migration on population growth and aging in Eastern European countries. Note that only Poland and Slovakia do not show negative population growth or depopulation (due to higher fertility). Also note that some countries (Bulgaria, Romania, Ukraine) demonstrate both negative natural increase (caused by low fertility) and negative net migration thus being in “double jeopardy” for rapid population aging. Some countries with high fertility like Moldova may experience rapid population aging due to high out-migration while immigration to Russia is able to alleviate negative consequences of low natural increase.

Demographic processes and population aging in the Russian Federation

Russia, with an elderly proportion of less than 14 percent in 2005, is rather young by European standards although it is older than the United States (12.3%).

Historical events and population aging in Russia. Population aging in Russia is affected by its past historical events, which are the best observed in the form of demographic pyramid. Figure 3 demonstrates a contemporary population pyramid of Russia, which resembles a shape of a Christmas tree due to sharp differences in the sizes of different birth cohorts.

FIGURE 3 ABOUT HERE

The irregular shape of the Russian demographic pyramid is a direct consequence of the following past events (Vassin 1996): (1) World War I and Civil War (1914-1922) resulting in decreased fertility during these years; (2) The famine of the early 1930s causing sharp decrease in the size of 1933-1934 birth cohorts as a result of both increased child mortality and decreased fertility; (3) World War II producing the largest distortions in the demographic pyramid including decrease of male cohorts born before 1927 and very small size of cohorts born in 1941-1945 due to low fertility. Very small birth cohorts born during the war period produced a fall in the number of births during the 1960s. Later these birth cohorts contributed to the decline in the number of births observed during the 1990s. All these historical events are reflected in the Russian demographic pyramid.

Recent changes in fertility and mortality. The shape of the 2002 pyramid is characteristic for the old population and is different from the 1989 pyramid, which had a broad base of young children born in the 1980s (Andreev et al. 2005). These population changes are a direct consequence of fertility decline in Russia during the economic transition period of the 1990s.

From 1950 to 1970, fertility in Russia changed from being amongst the highest in Europe (nearly three children per woman) to one of the lowest (1.8 children per woman in the cohort of 1945) (Avdeev and Monnier 1994; DaVanzo and Grammich 2001). In early 1980s the Soviet government introduced pronatalist policies, which resulted in temporary increase in fertility rates during 1982-1987 (DaVanzo and Grammich 2001). By the end of the 1980s, fertility pattern in Russia has progressed from a pattern of highly diverse family sizes to one in which the one or two-child family model has been widely adopted (Avdeev and Monnier 1994). It is believed that pronatalist measures of the Soviet government did not result in fundamental changes in fertility behavior but have been mainly a result of women spacing their births closer together rather than increasing the number of children that they ultimately have (DaVanzo and Grammich 2001). After 1990 fertility in Russia started to decrease with a rapid pace, most likely as a result of economic and political changes after break-up of the Soviet Union. Increase in the cost of living and the cost of raising children in particular resulted in impoverishment of many families with children. In 1989 poverty in Russia was heavily concentrated among the elderly. However in 2000, poverty became to a large extent a problem for people of work-active ages and their children (Gustafsson and Nivorozhkina 2004). Many Russian couples now cannot afford raising children and fertility in Russia now is among the

lowest in the world. There is a significant regional variability in fertility within Russia, with North Caucasus demonstrating the highest and big cities (Moscow, St. Petersburg) the lowest rates of fertility (DaVanzo and Grammich 2001).

Rapid decline of fertility in early 1990s coincided in time with a rapid increase of mortality. In 1991-1992 both trajectories crossed over forming a pattern, which is called now the “Russian cross” (see Figure 4) (Khalturina and Korotaev 2006).

FIGURE 4 ABOUT HERE

In addition to the lowest-low fertility, declining life expectancy is another substantial component of ongoing demographic crisis in Russia. Although life expectancy in Russia has been significantly improved from 1920 to 1960, after 1965 Russia experienced slow but steady decrease in life expectancy for both men and women (DaVanzo and Grammich 2001). This decline was stopped in 1985 with introduction of Gorbachev’s anti-alcohol campaign (Mesle and Shkolnikov 1995; Shkolnikov et al. 1998). Significant decrease of alcohol sales was a substantial component of this campaign. Demographic result of this antialcohol campaign was reduction of mortality (particularly among men) and increase in life expectancy by more than 3 years from 1985 to 1987 (DaVanzo and Grammich 2001). Gorbachev antialcohol campaign although successful from the view of public health results, was highly unpopular in Russia and has been folded by the late 1980s. At this time mortality started to grow again and from 1992 to 1994 life expectancy of Russian males dropped from 63.8 to 57.7 years. Female life expectancy dropped from 74.4 years to 71.2 years (Gavrilova et al. 2000). This decrease in life

expectancy coincided in time with introduction of painful market 'reforms' in Russia, leading to a rapid decrease in real wages and pensions, nearly complete loss of personal savings, and a tremendous increase in the poverty rate. The main causes of death that contributed to this mortality decline were diseases of the circulatory system, accidents, poisoning and injuries, diseases of the respiratory system (Notzon et al. 1998). After 1995, mortality in Russia demonstrated slow but stable decrease. However, in August 1998 Russia experienced another economic crisis (crash of the banking system) resulting in mass impoverishment. Shortly after this crisis mortality started to grow again and male life expectancy dropped from 61.3 in 1998 to 58.7 years in 2001, while female life expectancy dropped from 72.6 to 71.6 years during the same period (Gavrilova et al. 2000). In both cases population at working ages appeared to be the most vulnerable age group while children and the elderly were not significantly affected (Gavrilova et al. 2000; Notzon et al. 1998; Shkolnikov et al. 1998). The losses in life expectancy during 1992-94 were more than 5 years for males and 3 years for females compared to the life expectancy in pre-crisis 1991. This fall in life expectancy is beyond the peacetime experience of any industrialized country. After 2000 life expectancy in Russia stabilized at very low levels.

There are several explanations of the Russian mortality crisis of the 1990s. Increase in alcohol consumption is considered to be the major factor of mortality increase resulting in a rise of mortality from external causes (Anderson 2002; DaVanzo and Grammich 2001; McKee, Shkolnikov and Leon 2001; Nemtsov 1997, 2002; Pridemore 2002; Shkolnikov et al. 1998) Russian men practice alcohol drinking significantly more often than women and have very low life expectancy (gender gap in life expectancy in

Russia is the highest in the world). Gains in life expectancy during the Gorbachev antialcohol campaign were significantly higher for men than women, suggesting that alcohol plays a major role in the observed very high mortality of Russian men. Recent small increase in Russian life expectancy in 2006 many experts explain by temporary reduction of alcohol sales during Summer of 2006. Another potentially important cause of mortality increase after 1992 is psychological stress experienced by adult population during the transition period (Shkolnikov et al. 1998). The hypothesis of deteriorating medical care and public health system as a primary cause of mortality increase after 1992 did not find support from available data (Shkolnikov et al. 1998).

The most plausible explanation of rising mortality during the 1990s and current persistence of very high mortality in Russia is a hypothesis of population poverty and marginalization (Ivanova, Semyonova and Dubrovina 2004). Economic conditions of the early 1990s resulted in a rapid impoverishment of large groups of population. Individuals who failed to cope with economic changes lost jobs, housing, engaged in alcohol abuse and eventually became socially marginalized. Regional studies in Russia showed that socially less adapted persons (unemployed or those involved in low-skilled activities) are responsible for the majority (up to 90%) of deaths at working ages (Ivanova et al. 2004). Survey data demonstrate that poverty is the major factor of high cardiovascular mortality in Russia (Vagero and Kislitsyna 2005). The poorest fifth of the studied population were more than twice as likely as others to report heart symptoms (Vagero and Kislitsyna 2005). At the same time, other studies demonstrated that wealthy groups (e.g., persons having university/college degree) or population living in good socio-economic conditions (resident population of Moscow) have life expectancy comparable to that observed in the

developed countries (). It is difficult to estimate accurately the proportion of socially disadapted group in the total population but existing data indicate that it may comprise about 15-20% of population. This group appears to be responsible for very high mortality in Russia at working ages.

Most alcohol-related deaths occur in Russia in a narrow interval of 45-55 years (Gavrilova et al. 2005). Therefore, the elderly in Russia may be considered as a selected population, which is less prone to alcohol abuse. Indeed, mortality at older ages did not demonstrate significant increase during the 1990s and for men it already returned to its pre-crisis levels (Nolte et al. 2005). However physicians report a growing number of alcoholics among the elderly men after 1994 as a response to the social and economic crisis (Gafarov et al. 2003).

Currently Russia is experiencing a decline in the proportion of older people due to relatively small cohorts born during the World War II period, which comprise a sizable part of the older population. However, as the large postwar birth cohorts begin to reach age 65 after 2010, the percent elderly in the Russian Federation will rise markedly, likely reaching 20 percent by the year 2040 (United_Nations 2006b). Similar increase in the proportion of the elderly due to retirement of very large baby boom postwar generation is expected in the United States. During the period between the last two censuses of 1989 and 2002 the proportion of young people (below age 20) declined by 4.7 percent while the proportion of older people (60 years and over) increased by 3.2 percent (Andreev et al. 2005). Mean age of population increased by 3 years. What determined the population aging in Russia between 1989 and 2002 censuses? Andreev et al. (2005) estimated a contribution of different demographic processes in the population aging of Russia

between the two censuses. It was estimated that living population enumerated in 1989 should age during the intercensal period by 13.7 years. However part of this population did not survive to older ages thereby decreasing the mean population age by 5.5 years. Children born during this period helped to decrease the mean age of population by almost 5 years (their contribution could be higher if total fertility would not decline in the 1990s). Immigration of predominantly younger people also had some “rejuvenating” effect on the population of Russia. This process decreased the mean age of population by 0.2 years. According to Andreev et al. (2005), population aging in Russia could be less prominent if the levels of fertility and mortality would remain stable at the level of 1988 (mean age would increase by only 1 year instead of 3 years).

Regional pattern of population aging. Within Russia, the current level and pace of population aging vary widely by geographic region, and usually within regions as well (Andreev et al. 2005; Heleniak 2003). But virtually all regions of Russia are now experiencing growth in their numbers of elderly residents. The percent of population aged 60 and over in 2002 varied from 8 in the Far Eastern region to 21 percent in the Central region. For many years Central region had the highest proportion of the older population. Table 4 shows changes in median age of population between two censuses for total, urban and rural populations of Russia and its seven administrative territories (okrugs). Note that rural populations of the Central and North-Western regions are the oldest while rural populations of the Far Eastern and Southern regions remain to be the youngest regions in Russia. Thus the rural population of Russia has higher regional differentiation by the level of population aging compared to the urban population. On

average the urban population of Russia is slightly younger due to migration of youth to cities from rural areas.

TABLE 4 ABOUT HERE

Due to a combination of long-term demographic trends and processes (including migration) population aging in Russia is the strongest among the rural women. When the proportion of women aged 65 and over in Russia is 16 percent, some regions of Central and North-Western Russia have population of older women that exceeds 30 percent (Andreev et al. 2005).

Russian population remains to be relatively young compared to other European countries including countries of the Easter Europe. Currently Russia does not age rapidly but this situation will change after 2010 when numerous postwar generations reach age 60, which will result in a rapid aging of the Russian population.

Demographic profile of the older Eastern European populations

Feminization of aging. The fact that in most nations females have lower mortality than males in every age group and for most causes of death results in “feminization” of population aging. This problem is particularly acute in Russia and other FSU countries which demonstrate high male/female mortality differentials. For example, Russia demonstrates the highest gender gap in life expectancy in the world, which exceeds 13 years (Table 5). At very old ages (80 years) differences in mortality between men and

women in Russia decline and become even lower than in Europe (Table 5). On the other hand, countries of the Eastern Europe have lower male/female mortality differentials than in European region being particularly low in Bulgaria and Czech Republic (Table 5).

TABLE 5 ABOUT HERE

In 2005 in Russia, there were 16.8 million older women and 8.4 million older men aged 60 and over, or a sex ratio of 50 men for every 100 women. This is the lowest proportion of men in population aged 60 and over in the region. In 2007 in the Eastern Europe this ratio was equal to 57 men to 100 women and 69 men per 100 women in European region (Table 6).

TABLE 6 ABOUT HERE

Some countries (Bulgaria, Romania and Czech Republic) have higher male to female ratio in older population compared to the European region probably due to better longevity of men in Romania and Czech Republic and poor survival of older women in Bulgaria (Tables 5 and 6). The male to female ratio decreases with age reaching 34 men to 100 men for persons 80 and over in the Eastern Europe and only 27 in Russia (Table 6). Losses of men during the World War II also contributed to this sex disproportion of older populations. It is projected that in Russia this sex disproportion will be partially

alleviated in the future (Vassin 1996). For comparison, in the United States the male/female ratio in 2007 was equal to 78 for persons aged 60 years and over and 54 for persons 80 years and over (United_Nations 2007).

Aging of the oldest-old population. Another notable observation in the aging world is that aging population has itself been aging: the "oldest old" (people aged 80 and over) are now the fastest growing portion of the total population in many countries including European region (Gavrilov and Heuveline 2003). This process is observed in the Eastern Europe but the pace of the oldest-old population increase is not as rapid as in the United States and other industrialized countries. In Russia, from 1990 to 2005, the population 80 years and over increased by 12 percent and the population 60 to 79 years old increased by 8 percent. In the Eastern Europe the population 80 years and over increased by 13 percent from 1990 to 2005. In contrast, the population 60 to 79 years old increased by 5 percent. Compare these figures with the United States where the population of the oldest old increased by 59 percent during the same period.

The proportion of oldest-old in the older population increased from 1975 to 2005 in the countries of Eastern Europe with average annual increase of 3 percent, which was slower than in the European region (4 percent, see Table 7).

TABLE 7 ABOUT HERE

However, from 1995 to 2005, the proportion of oldest-old in older population decreased rather than increased in Russia, Ukraine and Belarus (Table 7). This phenomenon may be

explained by increasing mortality of older persons in these countries and structural effects of different sizes of birth cohorts. At the same time such countries as Bulgaria, Poland Moldova and Slovakia experienced rapid growth of the oldest old proportion among the older population.

Social and economic implications of population aging in the Eastern Europe

Population aging represents a challenge for public health (growing proportion of older people who need health assistance) and economic development (shrinking and aging of labor force, possible bankruptcy of pension systems). Rapid population aging of Russia and the Eastern European countries will result in a range of potential problems including growing economic pressure on countries' pension systems, higher demand for health care and an increasing tax burden on a shrinking working-age population (Heleniak 2003).

Increasing load on social welfare system. This problem is associated with the increase in the older population relative to the economically active population. As age structures change and older individuals become a proportionally greater part of national populations, there are social and political pressures on transfer systems with potential danger of the crisis of social support.

The potential support that elderly may receive from the working population can be measured by the potential support ratio: the ratio of population aged 15-64 years to that aged 65 years and over (Mujahid 2006). This ratio of economically active (working) population to the elderly dependent population is crucial for an understanding of intergenerational transfers, taxation policies, and saving behavior. It is used to estimate

the support base available to carry the burden of the older population. The ratio is measured as an inverse of age-old dependency ratio (Gavrilov and Heuveline 2003). Values of the potential support ratio for the countries of Eastern Europe are presented in Table 8.

TABLE 8 ABOUT HERE

A falling potential support ratio from 1975 to 2007 indicates a shrinking support base. It is interesting that all countries of the Eastern Europe with exception of Ukraine and Bulgaria still have higher potential support ratio than Europe. Potential support ratio assumes that people aged 15-64 are working and those aged 65 years and over are not. In reality older people may work or have other sources of income and support their adult children. For example Kuhn and Stillman (2004) studied interhousehold transfers during the transition period in Russia and found that net interhousehold transfers flow predominantly from elderly and “empty-nest” households to younger households. Transfers allowed older Russians to subsidize working-age families adjusting to post-Soviet labor market and help them to raise children (Kuhn and Stillman 2004). This became possible because older people received more stable income in the form of pension payments while people at working ages were subjected to all uncertainties and fluctuations of a free market.

Another indicator of potential support is a parent support ratio: a ratio of population aged 85 years and over to the population aged 50-64 years relating those aged 85 and over to their presumed offspring (Mujahid 2006). This indicator reflects a burden of

oldest-old population to their “offspring,” indicating the resource base of family support available to the oldest-old population. Table 8 shows uniform increase of the parent support ratio from 1975 to 2007 in the countries of Eastern Europe highlighting the growing need for an adequate care to the oldest old. The values of parent support ratio in the Eastern Europe are still much lower than in European region.

In the developed countries, rapid aging places strong pressure on social security programs. In the countries of Eastern Europe this problem is exacerbated by very low retirement age, particularly for women (see Table 9).

TABLE 9 ABOUT HERE

Eastern European countries inherited very generous and near universal pension systems from their Communist past based on “pay-as-you-go” (PAYG) principle. Benefits were based on years of service and not the amount of contributions paid. The non-FSU countries of Eastern Europe tried different approaches to restructuring their pension systems against a general background of political changes and acute financial constraints (Fultz and Ruck 2001). Most of them restructured existing PAYG systems and adopted a system of pension accounts based on individual contributions (Kritzer 2002).

Before the breakup of the Soviet Union, pensions in Russia were close to the average wage levels (DaVanzo and Grammich 2001). During 1990s, pensions fell to less than 30% of average wage value resulting in widespread impoverishment of older people (DaVanzo and Grammich 2001). Even these small pensions were not paid in time in

1996-1999. This problem was also exacerbated by wage arrears experienced by many working families in the 1990s. Data from the Russia Longitudinal Monitoring Survey (RLMS) showed that wage arrears had detrimental effects on the well-being of the elderly in these families (Richter 2006). Salaries in households with wage arrears dropped by almost two-thirds and poverty doubled. The elderly cut back on food expenses and the nutritional content of food consumption with regard to vitamins and minerals deteriorated. Functional limitations rose by 8% for men and 3% for women, and self-rated health declined by 2.5% for men and 0.5% for women (Richter 2006).

Difficulties with timely pension payments forced Russian government to make steps for reforming Soviet style pension system. This old system had several limitations (Maleva and Sinyavskaya 2005): (1) low level of pension payments, which were not adjusted for inflation. As a result, persons retired long ago had very small pensions compared to the recent retirees. (2) Low differentiation of pension benefits, which did not take into account past income; (3) Relatively low retirement age (60 years for men and 55 for women); (4) Common practice of early retirement (even earlier than 60 or 55 years) for many professional groups. Western researchers also mention lack of individual choice and lack of alternative pension financing as limitations of the Soviet pension system (Williamson, Howling and Maroto 2006), which probably is not considered to be a limitation by most Russians (only few Russians opted out of state pension financing and chose private pension funds during the recent pension reform). Since 1991 there were several attempts to reform pension system in Russia (Maleva and Sinyavskaya 2005). Finally in 2001, Russia selected the World Bank model of pension reform, which implements individual pension accounts (Maleva and Sinyavskaya 2005; Williamson et

al. 2006). The World Bank strongly recommended a transition from the existing defined benefit scheme to an alternative that included a notional defined contribution component (Williamson et al. 2006). The reform is currently underway, but it faces many difficulties besides population aging per se. The reform adopted in Russia was largely based on the system of accumulation of funds on personal pension accounts. Current actuarial forecasts in Russia show that the proportion of these funds in the total pension for young adults is very small and does not exceed 15%. Many young people in Russia are involved in informal jobs, which do not include any paperwork and hence no taxation and pension payments. It was also planned to reduce the early retirement practice and to replace it by professional pension systems. However difficulties in reaching agreement between state, employers and employees postponed the introduction of such pension systems. It was expected that the new pension system would encourage both employers and employees to participate in legal businesses thus increasing the contributions to the Pension Fund. However population surveys showed that this did not take place. Increase of retirement age meets very strong opposition in the Russian society, where lifespan of men does not even reach the statutory retirement age. The state monopoly in pension system management have not been decreased but rather been increased during the recent years (Maleva and Sinyavskaya 2005). Finally authors of the report note very high dependence of the Russian pension system on political decisions and political risks, which strongly affect its solvency (see Maleva and Sinyavskaya 2005 for more detail). Currently Russian pension system encounters numerous problems besides the population aging.

Living arrangements among the elderly in the Eastern Europe.

Population aging also causes changes in living arrangements resulting in increasing number of older people living alone (see Table 9). Since older persons have usually lower income with many living below the poverty line, population aging results in increasing poverty in many countries of the Eastern Europe. This is particularly the case for the countries of the Former Soviet Union (Russia, Ukraine, Belarus, Moldova) with small pensions, which are generally below the subsistence level. Economic needs may force older people to continue their work beyond the retirement ages (Table 9).

The consequence of very high male mortality in Russia and other FSU countries is a high proportion of non-married women at older ages: over sixty percent of women over age 60 in 2005 were not married. The proportion of non-married women was slightly lower in Bulgaria, Romania and Poland but still higher than in many industrialized countries (Table 9).

Table 10 shows proportion of persons living alone in selected Eastern European countries. Note high proportion of older people living alone in Czech Republic, which may reflect rather an adoption of western lifestyle than abandonment of the elderly. It also shows that unmarried people are more likely to live alone. Although relatively high proportion of older Russian women live alone, older Russian men are the least likely to live alone among the compared countries.

TABLE 10 ABOUT HERE

These data however are rather old and may not reflect the most recent tendencies in the living arrangements of older people. Such data were obtained during the survey conducted by the fund “Public Opinion” in Russia (Vovk 2006). According to the survey, there are no established social norms in regard to the co-residence of older people with their children in Russia. When asked about benefits of older people co-residence with their children and grandchildren 40-43% of respondents found more negative than positive aspects in such co-residence while 34-36% had an opposite opinion. The responses were similar for both older and younger respondents. On average slightly more respondents found negative aspects of co-residence with the elderly compared to those who found more positive aspects of such co-residence (Vovk 2006). Another survey of 1,500 respondents conducted in 2005 in Russia gives information on living arrangements among older people of different ages (Presnyakova 2006). According to the survey, 26% of people aged 60-69 years and 39% of those aged 70 years and over live alone. Among the oldest age group (70+) 29% live with a spouse, 30% live with children and 20% live with grandchildren. These data show that proportion of older people living alone increases with age. Table 11 demonstrates the same phenomenon for five selected countries. The highest proportion of the oldest-old living alone is observed in Czech Republic and the lowest proportion in Russia.

TABLE 11 ABOUT HERE

Proportion of older population living in institutions reflects a demand in long-term care but may be constrained by government abilities to provide sufficient funds for this kind

of services. Existing data on the proportion of institutionalized population by age presented in Table 11 refer to the early 1990s. The proportion of older people residing in institutions is higher in the oldest age group but is still much lower than in the Western European countries (De Vos and Sandefur 2002).

Rising demand for health services. One of the main challenges of an aging population is an increasing demand for health care services. Older people (oldest-old in particular) are prone to higher morbidity. As nations age, a shift in disease patterns become inevitable increasing societal burden demand for providing more resources to elders' health care.

Healthy life expectancy (HALE) can be used to assess differences in mortality and morbidity across countries and is interpreted as expected lifetime in full health (WHO 2004). Table 12 shows values of HALE at birth and at age 60 for countries of the Eastern Europe as well as expectation of lost healthy years at birth. Note that FSU countries have the lowest values of HALE among the countries of Eastern Europe.

TABLE 12 ABOUT HERE

At the same time, men and women in Russia, Ukraine and Belarus have the shortest life spent in a state of ill health because of high mortality at all ages. Shorter time spent in the state of ill health decreases overall burden on health care system in these countries. It was estimated that working-age mortality in Russia may be so high that the future pension obligations would be reduced to the levels sufficient for the nation to support current pension programs (DaVanzo and Grammich 2001).

Health surveys demonstrate consistently worse health in Russia compared to western countries. For example, survey conducted in Galesburg, Illinois and Moscow, Russia found that self-assessed health was good for 77% of Americans and only 6% of Russians (Jogerst et al. 2006), although Russian population was about ten years younger than American population with a mean age of 67 years and 78 years respectively. It is interesting that Sixty percent of Russians took no medications compared with 14% of Americans, but Russians reported more cardiovascular disease, angina, and hypertension (Jogerst et al. 2006). These differences may be partially explained by difficulties in getting access to medical care by older people in Russia (Sinyavskaya 2006). Although health care system in Russia includes free services, many pensioners report difficulties in obtaining qualified medical care (Sinyavskaya 2006).

Alcohol abuse and other lifestyle factors (tobacco smoking, malnutrition, low exercise) are usually mentioned as the main cause of high mortality and poor health in Russia and other FSU countries (Nolte et al. 2005). Indeed, WHO data show high prevalence of lifestyle risk factors in these countries. For example, prevalence of smoking among Russian (56.7%) and Ukrainian (66.8%) men is significantly higher than among Czech men (38.9%) (WHO 2007). Although consumption of alcohol in Russia reported by WHO is not the highest in Europe, Russian men tend to consume predominantly strong liquors (vodka), which are the most detrimental to health and drink in binges (McKee et al. 2001; Shkolnikov et al. 1998; Shkolnikov et al. 2002). DALY indicator is a useful approach to measure contribution of different causes to mortality and morbidity. DALYs for a disease or health condition are calculated as the sum of the years of life lost due to premature mortality (YLL) in the population and the years lost due to

disability (YLD) for incident cases of the health condition (WHO 2002). According to WHO data, the burden of cardiovascular disease accounted for almost one third of the overall burden of disease in Russia, Ukraine and Belarus while the impact of neuropsychiatric disease and cancer was significantly lower than in Western European countries (Nolte et al. 2005). Contribution of injuries into burden of disease was also unproportionally high in the FSU countries compared to the countries of Western Europe. World Health Report (WHO 2002) also provides data on contribution of major risk factors into the overall burden of disease using DALYs. Alcohol and tobacco use are the major factors of ill health for men in the FSU countries in contrast to obesity and tobacco use for men in Western Europe (WHO, 2002). Contribution of alcohol into ill health was higher and contribution of tobacco use was lower for FSU women compared to Western European women (WHO 2002).

However alcohol abuse is not the only factor of poor health among Russian men and women. Studies showed that economic hardship of the 1990s and poverty have detrimental effect on health, particularly for men. For example, during 1996-1999, many pensioners did not receive pensions for an extended period of time. RLMS data showed that among affected pensioners, poverty rates doubled, and the intake of calories and protein and the use of health services and medications declined significantly. These pensioners were also 5 percent more likely to die in the two years following the crisis (Jensen and Richter 2004). Another survey demonstrated that poorest fifth of the respondents were more than twice as likely as others to report heart symptoms. Problems in affording vegetables, meat or fish, clothes and footwear were linked to heart symptoms more closely than other economic indicators (Vagero and Kislitsyna 2005).

Summarizing this brief review of health in the countries of Eastern Europe, we may conclude that FSU countries lagged behind other countries of the Eastern Europe in both health indicators and reforms of their health care systems. Many countries of Eastern Europe (like Czech Republic or Poland) could successfully reform their health systems and made significant achievements in mortality reductions. FSU countries reformed their health systems in the direction of replacing free services by paid services, which made many of them unaffordable to less wealthy groups of population and older people in particular.

Projections of population aging in the 21st century

Before the 1980s the process of population aging was considered as an exclusive consequence of fertility decline and it was predicted that the pace of population aging would decrease after stabilization of fertility rates at some low levels. Rapid decline in mortality at older ages observed in developed countries in the last decades of the 20th century accelerated the process of population aging in these countries. Now human mortality is the key demographic component in projecting the size and composition of the world's future elderly population. Current and future uncertainties about changing mortality may produce widely divergent projections of the size of tomorrow's elderly population. The problem of uncertainty about the future changes in mortality is particularly acute for Russia and the countries of the Eastern Europe, which demonstrated periods of mortality growth and decline during the last two decades.

Table 13 shows observed and forecasted proportions of the elderly and the oldest-old in the countries of the Eastern Europe. Forecasted data correspond to the medium variant

of the UN demographic projections. The medium variant assumes that total fertility in all countries will converge eventually toward a level of 1.85 children per woman. Note that all countries with the exception of Czech Republic will have lower proportions of older age groups in 2030 than the total European population. Relatively high proportions of older people in 2030 are also expected in Hungary, Bulgaria, Poland, Slovakia and Ukraine.

TABLE 13 ABOUT HERE

An example from the Russia illustrates the range of future uncertainty about the size of tomorrow's oldest-old population. The United Nations projections estimated the proportions of people aged 60 and over in Russia to be 24.9 percent (medium fertility variant), 23.2 percent (high fertility variant), 27 percent (low fertility variant) and 25.9 (constant fertility variant). The differences in these projections result almost exclusively from the assumptions about fertility rates. Adult mortality rates are assumed to decline in all countries producing the smaller improvement the higher the life expectancy already reached.

According to the IIASA projections, from 2000 to 2050 the proportion of the world population above age 60 would increase from 10 to 22 percent. In the Western Europe it would increase from 20 to 35 percent for the same period (Lutz, Sanderson and Scherbov 2001). Around year 2050 the proportion of population above age 60 in the Eastern Europe would be approximately the same as in the Western Europe. The projected trends in the proportions of the elderly (60+) made by the United Nations are presented in

Figure 4. Note that by 2050 the population aging in the Eastern Europe will reach the total European levels. In Russia, however, the proportion of the elderly will remain to be lower compared to the European region.

Summary

Russia and most countries of the Eastern Europe lag behind the Western Europe in the degree of population aging. Low fertility is the major determinant of population aging in these countries. The role of migration varies across the countries and is a significant determinant of population aging in the countries experiencing high out-migration flows (like Bulgaria or Moldova). Until recently increasing longevity did not play a significant role in population aging in Russia and Eastern Europe. It is expected that longevity may become soon a significant determinant of population aging in the countries demonstrating a rapid decrease of mortality (Czech Republic, Slovakia, Poland). In the FSU countries effects of longevity on population aging is a possibility of remote future. The latter fact makes overall pressure on social welfare and health care systems caused by population aging less prominent compared to other industrialized countries.

Table 13. Dynamics of Population Aging in Russia and the Eastern Europe

Observed and Forecasted (Medium Variant) Percentages of the Elderly (60+ years) and the Oldest Old (80+ years) in Different Countries of the Eastern Europe: 1975, 2000 and 2030.

Country/Region	1975		2000		2030	
	60+	80+	60+	80+	60+	80+
Europe	16.4	1.6	20.3	2.9	29.7	6.0
Eastern Europe	14.4	1.3	18.6	2.0	26.4	4.1
Belarus	14.2	1.8	19.3	1.9	26.1	3.3
Bulgaria	16.1	1.4	22.0	2.1	29.5	5.2
Czech Republic	18.3	1.7	18.3	2.3	30.2	6.4
Hungary	18.3	1.7	19.8	2.5	28.4	5.6
Poland	13.8	1.2	16.6	2.0	27.6	4.9
Republic of Moldova	10.8	1.0	13.8	1.2	23.0	2.9
Romania	14.3	1.2	19.1	1.8	26.7	4.1
Russia	13.6	1.2	18.3	2.0	24.9	3.6
Slovakia	13.8	1.2	15.4	1.8	27.3	4.6
Ukraine	15.8	1.6	20.7	2.3	28.6	4.6
